RESEARCH ARTICLE

10.1002/2014PA002723

Key Points:

- Archaea other than marine Thaumarchaeota exert a minimal impact on most Eocene temperatures
- Tropical and high-latitude cooling during the descent towards the icehouse
- Carbon dioxide is the most likely driver of long-term Eocene cooling

Supporting Information:

- Texts S1 and S2, Figures S1–S4, and Tables S1–S4
- Data Set S1

Abstract The TEX₈₆ proxy, based on the distribution of marine isoprenoidal glycerol dialkyl glycerol tetraether lipids (GDGTs), is increasingly used to reconstruct sea surface temperature (SST) during the Eocene epoch (56.0–33.9 Ma). Here we compile published TEX₈₆ records, critically reevaluate them in light of new understandings in TEX₈₆ palaeothermometry, and supplement them with new data in order to evaluate long-term temperature trends in the Eocene. We investigate the effect of archaea other than marine Thaumarchaeota upon TEX₈₆ values using the branched-to-isoprenoid tetraether index (BIT), the abundance of GDGT-0 relative to crenarchaeol (%GDGT-0), and the Methane Index (MI). We also introduce a new ratio, % GDGT_{RS}, which may help identify Red Sea-type GDGT distributions in the geological record. Using the offset between TEX₈₆^H and TEX₈₆^L ($\Delta H-L$) and the ratio between GDGT-2 and GDGT-3 ([2]/[3]), we evaluate different TEX₈₆ calibrations and present the first integrated SST compilation for the Eocene (55 to 34 Ma). Although the available data are still sparse some geographic trends can now be resolved. In the high latitudes (>55°), there was substantial cooling during the Eocene (~6°C). Our compiled record also indicates tropical cooling of ~2.5°C during the same interval. Using an ensemble of climate model simulations that span the Eocene, our results indicate that only a small percentage (~10%) of the reconstructed temperature change can be ascribed to ocean gateway reorganization or paleogeographic change. Collectively, this indicates that atmospheric carbon dioxide (pCO_2) was the likely driver of surface water cooling during the descent toward the icehouse.

1. Introduction

Throughout the Phanerozoic, and possibly throughout geological time, the Earth's climate has oscillated between greenhouse and icehouse climate states, where greenhouse climates are characterized by high atmospheric carbon dioxide (pCO_2) [Pearson and Palmer, 2000; Pagani et al., 2005; Lowenstein and Demicco, 2006; Pearson et al., 2009], high sea surface temperatures (SST) [Pearson et al., 2007; Bijl et al., 2009; Hollis et al., 2012], and the absence of continental ice sheets [Francis and Poole, 2002; Contreras et al., 2013], and icehouse climates are characterized by the opposite: reduced pCO_2 , reduced SST, and presence of continental ice sheets [Zachos et al., 1992; Pearson and Palmer, 2000; DeConto and Pollard, 2003; Pagani et al., 2005; Lear et al., 2008; Zhang et al., 2013]. The most recent transition, from a greenhouse to an icehouse climate state, occurred during the Eocene-Oligocene transition (EOT; ~33.6–34.1 Ma). It is thought to have been driven by either a long-term decline in pCO_2 [Pagani et al., 2005; Zhang et al., 2013] and/or changes in ocean circulation and heat distribution as a result of ocean gateway reorganization [Kennett and Exon, 2004; Stickley et al., 2004; Bijl et al., 2013]. The generation of long-term, regional temperature records is essential for developing a more detailed picture of global cooling during the Eocene and elucidating the driving mechanisms responsible.

TEX₈₆, an organic palaeothermometer based upon the distribution of isoprenoidal glycerol dialkyl glycerol tetraethers (GDGTs) in marine Thaumarchaeota, has previously been used to reconstruct spatial and temporal patterns of oceanic cooling during the Eocene [Pearson et al., 2007; Burgess et al., 2008; Bijl et al., 2009; Hollis et al., 2009; Liu et al., 2009; Hollis et al., 2012; Bijl et al., 2013]. A recent TEX₈₆ core-top

calibration introduced two separate indices and calibrations for (1) the entire data set (GDGT ratio-1; $\text{TEX}_{86}^{\text{L}}$) and (2) a subset of the data set that excluded GDGT distributions from high-latitude sediments (GDGT ratio-2; $\text{TEX}_{86}^{\text{H}}$) [Kim *et al.*, 2010]. Kim *et al.* [2010] recommended applying $\text{TEX}_{86}^{\text{H}}$ when SSTs are estimated to have been above 15°C and $\text{TEX}_{86}^{\text{L}}$ where SSTs may have ranged below 15°C. However, this approach has been questioned [Taylor *et al.*, 2013], and it is unclear which of the two calibrations is most appropriate for a given setting. The most recent TEX_{86} calibration is based upon the original TEX_{86} [Schouten *et al.*, 2002] and calibrated to SST using a spatially varying, Bayesian regression model (BAYSPAR) [Tierney and Tingley, 2014].

The TEX_{86} proxy is based upon the assumption that GDGTs in sediments are largely derived from Thaumarchaeota living in the upper water column [Schouten *et al.*, 2002; Pearson and Ingalls, 2013]. However, Thaumarchaeota are not restricted to these settings and inputs of GDGTs to sediments from alternative sources will affect TEX_{86} SST estimates. For example, Groups I.1a and I.1b Thaumarchaeota are present in the terrestrial environment [Jurgens *et al.*, 1997; Ochsenreiter *et al.*, 2003] and can bias TEX_{86} SST estimates in areas with high terrigenous input [Hopmans *et al.*, 2004; Sluijs *et al.*, 2006; Weijers *et al.*, 2006b; Sluijs *et al.*, 2009]. Considerable work has also explored the potential for sedimentary GDGT production to affect TEX_{86} values. Particular interest has focused upon methanotrophic [Schouten *et al.*, 2003; Weijers *et al.*, 2011; Y. G. Zhang *et al.*, 2011] and methanogenic [Schouten *et al.*, 2002; Blaga *et al.*, 2009] archaea, yet these sources are rarely discussed in deep-time investigations.

As Thaumarchaeota live throughout the water column [Kamer *et al.*, 2001], it is also likely that subsurface archaea are exported to sediments [Pearson *et al.*, 2001; Shah *et al.*, 2008; Taylor *et al.*, 2013; Hernández-Sánchez *et al.*, 2014]. During the Eocene, unexpectedly large offsets between $\text{TEX}_{86}^{\text{H}}$ and $\text{TEX}_{86}^{\text{L}}$ ($\Delta\text{H-L}$) are observed above 15°C [Hollis *et al.*, 2012]. The reason for this is unclear, but it has been argued that it could, in part, reflect enhanced export of archaea living in the subsurface with elevated ratios of GDGT-2 to GDGT-3 ([2]/[3] ratios) [Taylor *et al.*, 2013; Kim *et al.*, 2015].

Paleotemperature reconstructions based on TEX_{86} assume that Thaumarchaeota in modern oceans are representative of those living in ancient settings. In most open ocean settings, thaumarchaeotal assemblages are dominated by Group I.1a Thaumarchaeota [Pester *et al.*, 2011] which are the putative biological source of the sedimentary GDGTs that define the TEX_{86} core-top calibration. In the Red Sea, however, phylogenetically distinct archaeal communities occur both above and below the thermocline [Eder *et al.*, 2002; Ionescu *et al.*, 2009; Qian *et al.*, 2011] and correspond to core-top sediments in which TEX_{86} values consistently overestimate satellite-derived SST by 6–8°C [Trommer *et al.*, 2009].

Here, we critically evaluate new and previously published GDGT distributions from Eocene sediments in order to understand the drivers of long-term cooling. Using the Methane Index (MI) [Y. G. Zhang *et al.*, 2011], % GDGT-0 [Sinninghe Damsté *et al.*, 2012], and the branched and isoprenoidal tetraether (BIT) index [Hopmans *et al.*, 2004; Weijers *et al.*, 2006b], we assess the impact of archaea other than marine Thaumarchaeota upon Eocene TEX_{86} values. We also propose a new index (%GDGT_{RS}) which we use to tentatively identify Red Sea-type GDGT distributions within the geological record. We use $\Delta\text{H-L}$ offsets and [2]/[3] ratios [Taylor *et al.*, 2013] to suggest the most appropriate TEX_{86} calibration for a given setting. Based on those observations, we use new and previously published TEX_{86} SST estimates to reconstruct spatial patterns of cooling during the Eocene (55–34 Ma) and earliest Oligocene (33–34 Ma). We compare our results with an ensemble of climate model simulations and investigate the most likely driving mechanism of long-term cooling during the descent toward the icehouse.

2. Methods

2.1. Data Compilation

TEX_{86} indices were compiled from Deep Sea Drilling Project (DSDP) Site 277 [Liu *et al.*, 2009], DSDP Site 511 [Liu *et al.*, 2009], Ocean Drilling Program (ODP) Site 628 [Liu *et al.*, 2009], ODP Site 803 [Liu *et al.*, 2009], ODP Site 925 [Liu *et al.*, 2009], ODP Site 929 [Liu *et al.*, 2009], ODP Site 998 [Liu *et al.*, 2009], ODP Site 1218 [Liu *et al.*, 2009], ODP Site 1172 [Bijl *et al.*, 2009], ODP Site 913 [Liu *et al.*, 2009], International Ocean Drilling Program (IODP) Site 1356 [Bijl *et al.*, 2013], Tanzania (Tanzania Drilling Project: TDP [Sites 2, 3, 7, 12, 13, and 18]) [Pearson *et al.*, 2007], New Zealand (Hampden Beach and Mid-Waipara River) [Burgess *et al.*, 2008; Hollis

Figure 1. Palaeogeographic reconstruction of the early Eocene (56.0–47.8 Ma) with the location of each Eocene site used in this compilation.

et al., 2009; Hollis *et al.*, 2012], and the Arctic Coring Expedition (ACEX) [Sluijs *et al.*, 2006; Sluijs *et al.*, 2009] (Figure 1). Where possible, we calculate and report the fractional abundance of all individual GDGTs (see supporting information). All GDGT-based indices are reported relative to the Geologic Time Scale 2012 (GTS2012) [Gradstein *et al.*, 2012].

2.2. GDGT Analyses

To complement our data compilation, we have determined GDGT distributions from ODP Site 929 (Ceara Rise), ODP Site 913 (Greenland Basin), South Dover Bridge (Atlantic Coastal Plain), and Hampden Beach (New Zealand) using methods similar to those of previous studies [Liu *et al.*, 2009; Hollis *et al.*, 2012] (Figure 1). Approximately 35–70 g of ground sediment was extracted via Soxhlet apparatus for 24 h using dichloromethane/methanol (2:1 vol/vol) as the organic solvent. The total lipid extract was subsequently separated over silica into neutral and fatty acid fractions using chloroform-saturated ammonia and chloroform:acetic acid (100:1 vol/vol), respectively [Dickson *et al.*, 2009]. The neutral fraction was further fractionated over alumina into apolar and polar fractions using Hexane:DCM (9:1 vol/vol) and DCM:MeOH (1:2 vol/vol), respectively. The polar fraction, containing the GDGTs, was dissolved in hexane/isopropanol (99:1, vol/vol) and passed through 0.45 μm PTFE filters. Fractions were analyzed by high-performance liquid chromatography/atmospheric pressure chemical ionization–mass spectrometry (HPLC/APCI-MS) using a ThermoFisher Scientific Accela Quantum Access. Normal phase separation was achieved on an Alltech Prevail Cyano column (150 mm \times 2.1 mm; 3 μm i.d.) with a flow rate of 0.2 ml min^{−1}. Initial solvent was hexane/isopropanol 99:1 (vol/vol), eluted isocratically for 5 min, and followed by a linear gradient to 1.8% isopropanol over 45 min. Analyses were performed in selective ion monitoring mode (SIM) to increase sensitivity and reproducibility, and [M+H]⁺ (protonated molecular ion) GDGT peaks were integrated.

2.3. GDGT-Based SST Indices

To reconstruct SST, Kim *et al.* [2010] invoke two separate TEX₈₆-based SST indices and calibrations. TEX₈₆^H uses the same combination of GDGTs as in the original TEX₈₆ relationship [Schouten *et al.*, 2002; Kim *et al.*, 2008] and is defined as

$$\text{GDGT index-2} = \log \frac{[\text{GDGT-2}] + [\text{GDGT-3}] + [\text{Cren.}]}{[\text{GDGT-1}] + [\text{GDGT-2}] + [\text{GDGT-3}] + [\text{Cren.}]} \quad (1)$$

where numbers refer to individual GDGT structures shown in Figure 2. GDGT index-2 is correlated to SST using the calibration equation:

$$\text{TEX}_{86}^{\text{H}}\text{-derived SST} = 68.4 \times (\text{GDGT index-2}) + 38.6 [\text{calibration error: } \pm 2.5^\circ\text{C}] \quad (2)$$

Figure 2. (a) Isoprenoidal and (b) branched glycerol dialkyl glycerol tetraethers used to calculate TEX_{86} and related indices.

$\text{TEX}_{86}^{\text{L}}$ employs a combination of GDGTs that is different from $\text{TEX}_{86}^{\text{H}}$, removing GDGT-3 from the numerator and excluding crenarchaeol regioisomer (Cren.) entirely:

$$\text{GDGT index-1} = \log \frac{[\text{GDGT-2}]}{[\text{GDGT-1}] + [\text{GDGT-2}] + [\text{GDGT-3}]} \quad (3)$$

GDGT index-1 is correlated to SST using the calibration equation:

$$\text{TEX}_{86}^{\text{L}}\text{-derived SST} = 67.5 \times (\text{GDGT index-1}) + 46.9 \text{ [calibration error: } \pm 4^{\circ}\text{C]} \quad (4)$$

Kim *et al.* [2010] argue that $\text{TEX}_{86}^{\text{L}}$ can be used to reconstruct SST across all temperature ranges, whereas $\text{TEX}_{86}^{\text{H}}$ is restricted to SST reconstruction above 15°C . Above 15°C , $\text{TEX}_{86}^{\text{H}}$ has a smaller standard calibration error, but both calibrations should yield similar temperatures and no significant offset should exist between them in the modern ocean ($\Delta\text{H-L} = 0$) [Taylor *et al.*, 2013]. Despite this, unexpectedly large $\Delta\text{H-L}$ offsets exist during the Eocene [e.g., Hollis *et al.*, 2012]. Hollis *et al.* [2012] also observed that Eocene $\text{TEX}_{86}^{\text{H}}$ SSTs are higher than those derived from inorganic proxies (i.e., Mg/Ca ratios and $\delta^{18}\text{O}$ values for planktic foraminifera). As a result, Hollis *et al.* [2012] developed an Eocene or “paleo” calibration based on the relationship between these inorganic SST proxies and GDGT ratio-2:

$$\text{SST} = 39.036 \times (\text{GDGT-ratio-2}) + 36.455 (r^2 = 0.87) \quad (5)$$

This relationship (defined as pTEX_{86}) [Hollis *et al.*, 2012] is derived from four Eocene records in which TEX_{86} indices and SSTs based on well-preserved, mixed layer planktic foraminifera have been determined for the same samples [Zachos *et al.*, 2006; Pearson *et al.*, 2007; Burgess *et al.*, 2008; Hollis *et al.*, 2009]. In the SW Pacific, this yields SST estimates that are consistently lower than $\text{TEX}_{86}^{\text{H}}$ but are generally similar to those derived using $\text{TEX}_{86}^{\text{L}}$ [Hollis *et al.*, 2012]. Taylor *et al.* [2013] argue that the $\Delta\text{H-L}$ offset is a function of the GDGT-2/GDGT-3 ratio ([2]/[3] ratio). As this ratio is markedly higher in deeper waters than the mixed layer [Taylor *et al.*, 2013], it is governed by export dynamics [Hernández-Sánchez *et al.*, 2014] but also partly related to water depth. For example, deep settings (>1000 m) in the modern ocean are characterized by low $\Delta\text{H-L}$ offsets (<3.0) and high [2]/[3] ratios (>5.0), whereas shallow settings (<1000 m) are characterized by high $\Delta\text{H-L}$ values (>3.0) and low [2]/[3] ratios (<5.0). Other recent developments in TEX_{86} palaeothermometry include the expansion of the core-top data set into subpolar and polar regions [Ho *et al.*, 2014] and the development of a spatially varying, TEX_{86} Bayesian regression model (BAYSPAR) [Tierney and Tingley, 2014]. In deep-time settings, BAYSPAR searches the modern core-top data set for TEX_{86} values which are similar to the measured TEX_{86} value and draws regression parameters from these modern “analogue” locations. SSTs are derived using an online graphical use interface (GUI) (www.whoi.edu/bayspar) [Tierney and Tingley, 2014]. Using this approach, an Eocene high-latitude site will draw analogues from a modern-day midlatitude site and so on. However, BAYSPAR does not resolve the problem of high $\Delta\text{H-L}$ offsets, as the SSTs tend to be similar to those derived from $\text{TEX}_{86}^{\text{H}}$ [Tierney and Tingley, 2014]. This is not surprising as BAYSPAR is based upon the original TEX_{86} ratio.

2.4. Other GDGT-Based Indices

A number of indices have been developed to screen for potential secondary influences on TEX_{86} . The ratio of branched GDGTs to crenarchaeol (Figure 2) in marine and lacustrine sediments is a function of terrestrial input, expressed as the Branched versus Isoprenoid Tetraether (BIT) index:

$$\text{BIT} = \frac{\text{Ia} + \text{IIa} + \text{IIIa}}{\text{Ia} + \text{IIa} + \text{IIIa} + [\text{Crenarchaeol}]} \quad (6)$$

Numbers refer to individual GDGT structures shown in Figure 2. It has been argued that TEX_{86} estimates with BIT values >0.3 should not be used for SST reconstruction due to the potential influence of soil-derived GDGTs on temperature estimates [Weijers *et al.*, 2006b]. Although the BIT has been applied within deep-time settings [Sluijs *et al.*, 2011; Jenkyns *et al.*, 2012], it is unclear whether a threshold of 0.3 remains applicable.

The Methane Index (MI) was proposed to distinguish the relative input of methanotrophic Euryarchaeota versus ammonia-oxidizing Thaumarchaeota in settings characterized by gas-hydrate-related anaerobic oxidation of methane (AOM) [Pancost *et al.*, 2001; Wakeham *et al.*, 2003; Stadnitskaia *et al.*, 2008; Y. G. Zhang *et al.*, 2011]:

$$\text{MI} = \left(\frac{[\text{GDGT-1}] + [\text{GDGT-2}] + [\text{GDGT-3}]}{[\text{GDGT-1}] + [\text{GDGT-2}] + [\text{GDGT-3}] + [\text{Crenarchaeol}] + [\text{Cren.}]} \right) \quad (7)$$

High MIs (>0.5) reflect high rates of gas-hydrate-related AOM and low values (<0.3) suggest normal sedimentary conditions (i.e., no appreciable AOM input); by extension, TEX_{86} values should be excluded when MI values >0.5 .

Sedimentary archaeal methanogens can synthesize GDGT-0, as well as smaller quantities of GDGT-1, GDGT-2, and GDGT-3 [Koga *et al.*, 1993; Weijers *et al.*, 2006a]. The %GDGT-0 index can be used to qualitatively evaluate the contribution of methanogenic archaea to the sedimentary GDGT pool:

$$\% \text{GDGT-0} = ([\text{GDGT-0}] / ([\text{GDGT-0}] + [\text{Crenarchaeol}])) * 100 \quad (8)$$

%GDGT-0 values from thaumarchaeotal enrichment cultures fall below 67%, such that an additional, potentially methanogenic, source of GDGT-0 is likely when %GDGT-0 values exceed this threshold. Blaga *et al.* [2009] and Sinninghe Damsté *et al.* [2012] argue that TEX_{86} values become unreliable in lacustrine settings when %GDGT-0 values $>67\%$, possibly because such a large methanogen input also contributes additional GDGT-1, GDGT-2, and GDGT-3 that can bias TEX_{86} values. However, it is unclear if a similar threshold applies to marine sediments.

2.5. Statistical Analysis

During the Eocene, TEX_{86} SST records have different sampling densities and/or span different intervals [Pearson *et al.*, 2007; Burgess *et al.*, 2008; Bijl *et al.*, 2009; Hollis *et al.*, 2009; Liu *et al.*, 2009; Hollis *et al.*, 2012; Bijl *et al.*, 2013]. To address this problem, time series which spanned the majority of the investigated time window (i.e., ODP 925, ODP 929, ODP 913, ODP 1172, IODP 1356, TDP, SDB, Mid-Waipara, and Hampden Beach) were grouped into low- ($<30^\circ$) or high-latitude ($>55^\circ$) bins. Using TEX_{86}^H each time series was then turned into a relative temperature (ΔT) by comparison to the warmest temperature in that time series. In order to determine the long-term mean SST evolution in each bin (high and low latitudes) with an associated uncertainty, separate nonparametric LOESS regressions were fitted to both the low- and high-latitude TEX_{86}^H ΔSST compilations using the R software package (<http://www.R-project.org/>). The degree of smoothing (i.e., the span term) was optimized for each time series using generalized cross validation, and an uncertainty envelope ($\pm 95\%$ confidence intervals) was calculated based upon the observed scatter of data around the best fit line. Sequential removal of one time series at a time (jackknifing) was also performed to examine the influence of each record on the long-term mean SST (see supporting information).

2.6. Modeling Setup

HadCM3L, a modified version of the UKMO Unified Model HadCM3 [Gordon *et al.*, 2000] fully coupled Atmosphere-Ocean General Circulation model (AOGCM), was employed within this study. The atmospheric and oceanic components of the model comprise a resolution of 2.5° by 3.75° , with 19 vertical levels in the atmosphere and 20 vertical levels in the ocean. Four time slice simulations were constructed utilizing high-

Figure 3. Histogram of BIT indices from open-marine core-top sediments (black) [Schouten *et al.*, 2013] and Eocene and Oligocene sediments (grey bars). Line represents the normal distribution curve for modern and Eocene and Oligocene BIT indices.

resolution paleogeographic boundary conditions under the framework of Markwick and Valdes [2004] representing the Ypresian (56.0–47.8 Ma), Lutetian (47.8–41.3 Ma), Bartonian (41.3–38.0 Ma), and Priabonian (38.0–33.9 Ma) geological stages and run for 1422 model years in total to allow surface conditions to approach equilibrium, reducing the error from model drift relative to shorter simulations (see Figure S5). Mean climate state is produced from the final 50 years of the simulation. Following an initial 50 years at 280 ppmv, atmospheric CO₂ is prescribed at 1120 ppmv (4× preindustrial level) for each simulation and with an appropriate solar constant [Gough, 1981] representative of each geologic stage defined. The initial ~500 years of the model simulations have a purely baroclinic ocean circulation to ensure stability during spin-up; the barotropic circulation is initialized after 500 years. The barotropic solver in the ocean model requires the definition of continental islands, around which the net ocean flow is nonzero; the defined islands in the model are

shown in Figure S6. Note that Antarctica has not been defined as an island in any of these simulations, resulting in a net ocean flow of zero around the margins of Antarctica, even though the palaeogeographic reconstruction implies a possible pathway for circum-Antarctic transport. Due to the small latitudinal extent and shallow depth of the Drake's and Tasman gateways at this time, we do not expect this to greatly affect our results. More details of the climate model itself are described in Loftson *et al.* [2014]; their simulation 4 × DYN is carried out with an identical model to the one used here.

3. Results and Discussion

For each site, including new and previously published data sets, we have determined TEX₈₆ SSTs during the Eocene and the Oligocene. All of these data sets are described in detail within the supporting information. Using a combination of parameters (BIT, MI, %GDGT-0), we investigate the sedimentary GDGT distributions and discard samples that are potentially problematic with respect to those prospective criteria (see sections 3–5 and supporting information). We then compare ΔH-L offsets against [2]/[3] ratios to explore the applicability of TEX₈₆^L before investigating spatial patterns of cooling during the Eocene (see section 6). Based upon our findings, we also reinvestigate cooling trends during the EOT (see section 7).

3.1. Impact of Terrestrial Input Upon Eocene TEX₈₆ Values

The observation that branched GDGTs occur predominantly in soils whereas crenarchaeol occurs predominantly in the marine environment led to the development of the branched-to-isoprenoidal tetraether (BIT) index [Hopmans *et al.*, 2004]. Although this was originally used to elucidate the relative input of terrestrial organic matter into the marine realm, it can also provide insights into the efficacy of TEX₈₆ estimates [Hopmans *et al.*, 2004; Weijers *et al.*, 2006b; Fietz *et al.*, 2011]. Weijers *et al.* [2006b] show that when BIT values exceed 0.2–0.3, temperature estimates are ~1°C higher than expected, and when BIT values exceed 0.4, temperature estimates can be >2°C higher. However, those observations are specific to that depositional system (the Congo Fan), and the impact of terrigenous GDGTs on reconstructed SST will depend on the nature and temperature of the source catchment. Using our Eocene and Oligocene compilation, we examine the apparent effect of terrestrial input upon TEX₈₆ SST estimates.

BIT values from the modern core-top data set do not exceed 0.25 in marine settings [Schouten *et al.*, 2013], with average values of 0.03 ($n=278$; $\sigma=0.03$) (Figure 3). In the Eocene and Oligocene, BIT values associated with TEX₈₆ data are higher with an average of 0.27 ($n=552$; $\sigma=0.19$) (Figure 3), likely arising from the fact that many of the Eocene sites from which TEX₈₆ records are derived are proximal to land. Many of these proximal settings, such as Tanzania and Seymour Island (Figure 1), do exhibit large temperature deviations (>5°C) when BIT indices are > 0.4 [Pearson *et al.*, 2007; Douglas *et al.*, 2014]. Sluijs *et al.* [2006] suggested that enhanced terrestrial input of GDGT-3 preceding the PETM at IODP Site 302

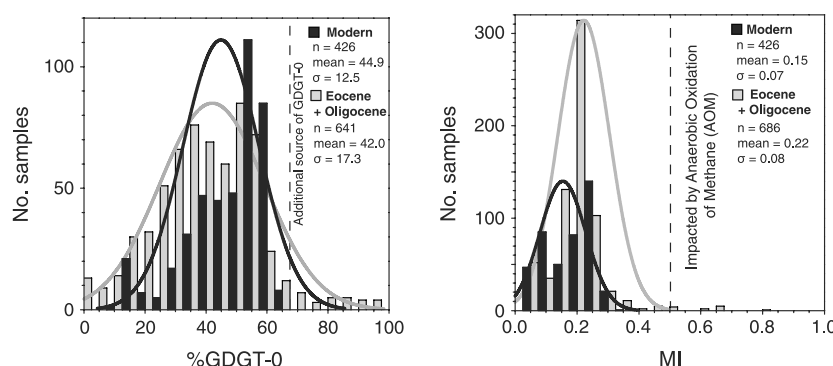

Figure 4. Histogram of (left) %GDGT-0 and (right) MI values from the core-top data set (black) [Trommer *et al.*, 2009; Kim *et al.*, 2010] and Eocene and Oligocene sediments (grey bars). Line represents the normal distribution curve for modern and Eocene and Oligocene %GDGT-0 and MI indices.

(ACEX; Figure 1) resulted in a significant temperature deviation. They removed GDGT-3 from the original TEX_{86} and developed a new index (TEX_{86}') which was calibrated to the modern core-top data set [Sluijs *et al.*, 2006, 2009]. However, we suggest that elevated GDGT-3 is not the only impact of terrigenous OM inputs on isoprenoidal GDGT distributions; i.e., an increase in GDGT-3 due to terrestrial input will also be associated with an increase in the abundance of other isoprenoidal GDGTs. As a result, we argue that TEX_{86}' is not a reliable alternative to SST reconstruction when terrestrial input is high.

TEX_{86} SST estimates from some deep (e.g., ODP Site 929 and ODP Site 925) and shallow (e.g., South Dover Bridge) water settings are relatively unaffected by enhanced terrestrial input. Intriguingly, the few sediment samples from those sites with high BIT values (>0.4) generally yield similar SSTs as those with low BIT values (<0.1). This could be fortuitous, with terrigenous input not causing significant deviations from marine distributions, but it does suggest that the threshold of 0.4 is conservative in some settings.

3.2. Impact of Archaeal Methanogenesis and Methanotrophy Upon Eocene TEX_{86} Values

Considerable work has suggested that sedimentary GDGT production can affect TEX_{86} values and subsequent climate interpretation [Blaga *et al.*, 2009; Y. G. Zhang *et al.*, 2011; Weijers *et al.*, 2011]. Anaerobic methane oxidizing Euryarchaeota, which synthesize isoprenoidal GDGTs containing 0–3 cyclopentane moieties [e.g., Pancost *et al.*, 2001], can affect TEX_{86} values at active cold seeps [Pancost *et al.*, 2001; Y. G. Zhang *et al.*, 2011] and possibly in sediments characterized by diffusive methane flux [Aquilina *et al.*, 2010; Weijers *et al.*, 2011]. Methanogenic archaea, which synthesize small quantities of GDGT-1, GDGT-2, and GDGT-3 [Koga *et al.*, 1993; Weijers *et al.*, 2006b], are also present in marine sediments. Currently, there is no evidence that they impact marine TEX_{86} values although they do appear to affect lacustrine TEX_{86} values [Blaga *et al.*, 2009; Powers *et al.*, 2010; Sinninghe Damsté *et al.*, 2012].

Figure 4a shows %GDGT-0 values for the modern core-top data set and our Eocene compilation. In the modern core-top data set, %GDGT-0 values span a broad range (9–65%, $n=426$) with an average of 45% ($\sigma=12.5$). This is expected for core-top sediments unlikely to have been affected by methane cycling [Martens and Berner, 1974]. Higher values occur in deeper sediments [Pancost *et al.*, 2008; Blaga *et al.*, 2009] and are associated with the occurrence of ^{13}C -depleted acyclic biphytanes ($\delta^{13}\text{C}$: -21‰ to -26‰) (note that depleted relative to thaumarchaeal-derived biphytanes ($\delta^{13}\text{C}$: -20‰ to -22‰)) [Schouten *et al.*, 1998; Pancost *et al.*, 2008]. This indicates that GDGT-0 is likely derived from methanogens in deeper horizons. Eocene %GDGT-0 values span a larger range (5 to 97; $n=641$), although the average %GDGT-0 value is similar to that observed in modern core-top sediments (42%; $\sigma=17$) (Figure 4a). The majority of samples ($>90\%$) fall below 67%, suggesting that methanogenic contributions are also relatively minor during the Eocene. In modern surface sediments, %GDGT-0 exhibits a positive correlation with latitude ($r^2=0.87$) and $\text{TEX}_{86}^{\text{H}}$ -derived SST ($r^2=0.55$). Despite some uncertainties in the accuracy of palaeolatitude estimates [e.g., Self-Trail *et al.*, 2012], Eocene %GDGT-0 values exhibit a weaker correlation with latitude ($r^2=0.43$) and $\text{TEX}_{86}^{\text{H}}$ -derived SST ($r^2=0.36$). This suggests an additional, potentially methanogenic, source of GDGT-0 in older sediments and provides further justification for the exclusion of GDGT-0 in TEX_{86}

palaeothermometry [Schouten *et al.*, 2002]. However, the actual impact on Eocene reconstructed temperatures appears to be minor. Only 7% of the Eocene data set yields %GDGT-0 values in excess of 67%, suggesting the presence of an additional, potentially methanogenic, source of GDGT-0. Some of these samples (i.e., ODP Site 913) also contain 2,6,10,15,19-pentamethylcosane (PMI), a common methanogen [Brassell *et al.*, 1981; Schouten *et al.*, 1997] and anaerobic methanotroph biomarker [Thiel *et al.*, 2001], and provide independent evidence for methane cycling at this site.

Several sedimentary sequences contain rather variable %GDGT-0 values, sometimes in adjacent sediments (e.g., Ceara Rise), perhaps as a result of localized bioturbation. In those cases, samples with high %GDGT-0 values do not yield significantly ($<2^{\circ}\text{C}$) different temperature estimates than samples with lower %GDGT-0 values. This suggests that sedimentary methanogenesis does not impact TEX_{86} SST estimates. This contrasts with observations made in lacustrine settings [Blaga *et al.*, 2009; Sinninghe Damsté *et al.*, 2012]. We suggest this is because GDGT-0 and GDGT-1, and possibly GDGT-2 and GDGT-3, co-occur in terrestrial settings [Pancost and Sinninghe Damsté, 2003; Weijers *et al.*, 2006a; Huguet *et al.*, 2010], whereas the production of GDGT-0 by methanogens in marine settings is not associated with significant production of GDGT-1 or GDGT-2 (or any other GDGTs used in the TEX_{86} palaeothermometer).

In the modern core-top data set, the Methane Index (MI) spans a narrow range (0.03–0.23) and averages 0.15 ($n = 426$; $\sigma = 0.07$) (Figure 4b). MIs exceed 0.3 in $< 1\%$ of samples and do not exceed 0.5. As with %GDGT-0 values, this is expected for core-top sediments which are likely unaffected by methane cycling [Martens and Berner, 1974]. In gas-hydrate-impacted and/or methane-rich environments, MIs are higher (>0.6) and span a larger range (~ 0.6 – 1.0). In such settings, high MIs are associated with the presence of ^{13}C -depleted biphytanes, providing further evidence for a methanotrophic source [Wakeham *et al.*, 2003; Wakeham *et al.*, 2004; Bouloubassi *et al.*, 2006; Pancost *et al.*, 2008; Y. G. Zhang *et al.*, 2011]. Elevated MIs also occur in older sediments of continental marginal settings characterized by high sedimentation rate and organic matter flux [Aquilina *et al.*, 2010; Weijers *et al.*, 2011]. MIs span a larger range (0.08–0.82) in our Eocene and Oligocene data set (Figure 4b; $n = 686$) and yield a slightly higher average value (0.22; $\sigma = 0.08$) than modern core-top sediments. MIs exceed 0.3 in $\sim 8\%$ of samples and exceed 0.5 in $< 2\%$ of samples, suggesting that most Eocene and Oligocene sediments, despite their continental margin locations, are relatively unaffected by diffusive methane flux and associated anaerobic oxidation of methane.

In the Eocene and Oligocene data set, a nonlinear, positive correlation exists between MI and %GDGT-0 (Figure S1). This is expected because sediment profiles characterized by methanogenesis will likely also have experienced some amount of anaerobic oxidation of methane [Sivan *et al.*, 2007]. This relationship is almost certainly driven by methane cycling rather than temperature, because the latter—by decreasing %GDGT-0 and increasing MIs—would yield a negative rather than positive correlation.

4. Red Sea-Type GDGT Distributions

In the modern core-top calibration, sediments from the Red Sea yield much warmer TEX_{86} SST estimates than observed values [Trommer *et al.*, 2009; Ionescu *et al.*, 2009] and are excluded from the global core-top calibration data sets of Kim *et al.* [2008] and Kim *et al.* [2010] but not the BAYSPAR calibration data set of Tierney and Tingley [2014]. Red Sea GDGT distributions are characterized by a low fractional abundance of GDGT-0 relative to Crenarchaeol regioisomer (Cren.). To identify a typical Red Sea-type distribution within the geological record, we propose the following ratio:

$$\% \text{GDGT}_{\text{RS}} = ([\text{Cren.}]/([\text{GDGT-0}] + [\text{Cren.}])) * 100 \quad (9)$$

However, we propose this only as an approximate evaluation tool, because other factors, such as temperature [Schouten *et al.*, 2002; Kim *et al.*, 2010], can affect %GDGT_{RS} indices (see later). Thus, we suggest it is initially employed to identify sediments with unusually low amounts of GDGT-0 relative to crenarchaeol regioisomer. Further evaluation of a putative Red Sea-type GDGT signature can be based on the entirety of the GDGT distribution [Trommer *et al.*, 2009].

%GDGT_{RS} values from the modern core-top data set ($n = 396$) [Kim *et al.*, 2010] do not exceed 24, except for the Red Sea, where values range from 32 to 59 ($n = 30$; Figure S2) [Trommer *et al.*, 2009]. As such, we propose that a Red Sea-type contribution should be considered for %GDGT_{RS} > 30 . In our Eocene compilation, these

Figure 5. Changes in temperature and salinity across the PETM at ODP Site 1172. (a) SST derived from TEX_{86}^H . (b) %GDGT_{RS} values. (c) The percentage of *Goniiodomoidae*, a hypersaline dinocyst [Sluijs et al., 2011]. Grey area denotes a Red Sea-type GDGT distribution.

River and Wilson Lake [Sluijs and Brinkhuis, 2009]. At all three sites, the occurrence of hypersaline dinocysts coincides with an increase in %GDGT_{RS} values. The presence of *Eocladopyxis* in the Recent has been explained by hyperstratification and the development of lagoonal conditions in the open ocean [Reichert et al., 2004; Sluijs and Brinkhuis, 2009]. At Mid-Waipara River, the dinocyst genus *Homotryblum*, a similar “lagoonal” indicator genus, is also present in low abundances during the early Eocene [Hollis et al., 2009] while other high-salinity, lagoonal dinocysts, such as *Heteraulacacysta* and *Polysphaeidium*, are identified during the PETM at Bass River and Wilson Lake [Sluijs and Brinkhuis, 2009]. Although the presence of hypersaline and/or lagoonal dinocysts is consistent with an increase in salinity, they rarely dominate the dinocyst assemblage [e.g., Sluijs et al., 2011] and it is possible that other factors exert a control upon Red Sea-type GDGT distributions.

Pure cultures of *Nitrosopumilus Maritimus*, a marine group I.1a thaumarchaeon, indicate that nutrient availability can influence GDGT distributions [Elling et al., 2014]. However, this contrasts with Trommer et al. [2009] who correlated Red Sea TEX_{86} values with nitrate concentrations at 100 m depth and found no obvious correlation. Alternatively, Kim et al. [2015] argue that modern Red Sea GDGT distributions originate from a deep-water (>1000 m) thaumarchaeotal community. Using core-top sediments from the Mediterranean and the Red Sea, Kim et al. [2015] recently developed a regional TEX_{86} SST calibration for deep-water (>1000 m), restricted basins. This yields lower TEX_{86} SSTs, both in the modern and during the Eocene. However, as Eocene Red Sea-type GDGT distributions are restricted to shallow water settings (typically <500 m), this calibration is deemed unsuitable here.

high %GDGT_{RS} values are common, widespread and range up to 70. During the Bartonian (41.3–38.0 Ma) and Priabonian (38.0–33.9 Ma), high %GDGT_{RS} values are confined to low-latitude sites (i.e., Tanzania). There, %GDGT_{RS} values are highly variable and exhibit no correlation with TEX_{86}^H SSTs. High %GDGT_{RS} values are especially common during times of elevated warmth (Figure S4). During the Early Eocene Climatic Optimum (EECO), high %GDGT_{RS} values become more geographically widespread, occurring at ODP Site 1172 [Bijl et al., 2009], Mid-Waipara [Hollis et al., 2009, 2012], Hampden Beach (this paper), and South Dover Bridge (this paper). At these sites, %GDGT_{RS} values gradually increase during the EECO, attain highest values during peak EECO warmth, and then gradually decrease following the EECO (Figure S4). Similarly, %GDGT_{RS} values increase at the onset of the PETM at Wilson Lake [Zachos et al., 2006; Sluijs et al., 2007], ODP Site 1172 [Sluijs et al., 2011] (Figure 5), and South Dover Bridge (this paper). GDGT-0 was not detected at Bass River [Sluijs et al., 2007; Sluijs and Brinkhuis, 2009]. Unfortunately, it appears that most of the Red Sea GDGT characteristics are indistinguishable from those expected for temperatures in excess of ~30°C (based on projecting correlations to temperatures beyond the modern limits). Therefore, we cannot currently untangle these effects on GDGT distributions in the sedimentary record.

Aside from temperature, the underlying ecological controls that govern the occurrence of these distributions remain unclear. At ODP Site 1172, the dinocyst genus *Eocladopyxis*, a member of the extant family Goniiodomidae that mainly inhabits low-latitude lagoonal environments, peaks during the PETM and the EECO [Sluijs et al., 2011] (Figure 5). A peak in *Eocladopyxis* spp. also occurs prior to and immediately after the onset of the PETM at Bass

Figure 6. Interrogating GDGT distributions. Samples derived from (1) Mid-Waipara River, (2) ODP Site 929, (3) ODP Site 925, and (4) Hampden Beach.

Intriguingly, high %GDGT_{RS} values and Red Sea-like GDGT distributions also occur in Mesozoic sediments, including in Oceanic Anoxic Event 1b sediments deposited at ODP Site 1049 [Kuypers *et al.*, 2001; Kuypers *et al.*, 2002]. There, a range of biomarker evidence has shown that deposition of organic-rich sediments represents an unusual and widespread expansion of archaea [Kuypers *et al.*, 2002]. The most diagnostic biomarkers for OAE1b archaeal assemblages, i.e., tetramethylcosane (TMI), have not been reported for the Eocene sediments discussed here nor the Red Sea. This could provide additional evidence for extreme Palaeogene and Mesozoic warmth; i.e., they reflect additional changes in the GDGT distribution beyond those reflected by TEX₈₆ values. Alternatively, they could reflect the same factors that influence Red Sea distributions and that overestimate SST. As Red Sea GDGT characteristics are indistinguishable from those expected for temperatures in excess of ~30°C; we continue to include high %GDGT_{RS} values within our long-term Eocene compilation.

5. Interrogating GDGT Distributions

BIT, %GDGT-0, MI, and %GDGT_{RS} are useful tools which can be used to flag potentially problematic TEX₈₆ values. However, there are limitations to a single numerical representation of these complex GDGT distributions. Figure 6a shows two sets of Eocene GDGT distributions with identical TEX₈₆ values (0.70). Sample 2 has a much higher %GDGT-0 value than Sample 1 and suggests an additional, potentially methanogenic, source of isoprenoidal GDGTs. Otherwise, the GDGT distribution is very similar to Sample 1 and suggests the SST reconstructions are valid. In Figure 6b, Samples 3 and 4 also have identical TEX₈₆ values (0.83) but different %GDGT_{RS} values, Sample 4 being characterized by a Red Sea-type GDGT distribution. As Red Sea-type GDGT distributions fall off the core-top calibration line for TEX₈₆^H [Schouten *et al.*, 2002; Kim *et al.*, 2010], this sample from Hampden Beach could overestimate SST (see section 4).

This translation of a complex GDGT distribution into a single TEX₈₆ value can also be problematic for the BAYSPAR approach. BAYSPAR searches the modern core-top data set for TEX₈₆ values that are similar to the measured TEX₈₆ value and draws regression parameters from these modern “analogue” locations. When a TEX₈₆ value exceeds 0.75, BAYSPAR typically draws regression parameters from the modern-day Red Sea. This assumes the ancient GDGT distribution is similar to the modern-day Red Sea; however, there are a number of Eocene and Oligocene localities where high TEX₈₆ values (>0.75) are not characterized by a Red Sea-type GDGT distribution (e.g., ODP 628, ODP 803, and ODP Site 925). In these samples, the Red Sea is an inappropriate analogue for a warm, subtropical site [Tierney and Tingley, 2014] and highlights the need to investigate the entire GDGT distribution before reconstructing SST.

6. Descent Toward the Icehouse

6.1. Comparison of GDGT-Based SST Proxies for the Eocene

The following section focuses upon SST estimates derived using TEX₈₆^H, TEX₈₆^L and pTEX₈₆ (see later). However, there are a number of other TEX₈₆ calibrations which merit further discussion. The current mesocosm calibration extends to 40°C [Wuchter *et al.*, 2004; Kim *et al.*, 2010] and may be preferable in low-

latitude “greenhouse” environments. However, in mesocosm studies, the fractional abundance of the crenarchaeol isomer is ~14 fold lower than expected and we thus argue against applying this calibration in deep-time settings. The application of a linear [Schouten *et al.*, 2002; Tierney and Tingley, 2014], logarithmic [Kim *et al.*, 2010] or reciprocal [Liu *et al.*, 2009] calibration will also impact SST reconstructions, particularly in low-latitude greenhouse environments. However, the linear calibration yields unrealistically high SST values (>30°C) during the Holocene [Kim *et al.*, 2010], and we therefore argue against its application in modern and ancient (sub)tropical climates. BAYSPAR, which also utilizes a linear calibration, does not appear to yield unrealistically high SST values during the Quaternary [e.g., Tierney and Tingley, 2014]; however, it does not formally address regional/oceanographic variations in deeper time reconstructions. This is because the analogue is generated by sampling within TEX₈₆ space (as discussed in section 2.3) rather than on the basis of oceanographic (productivity regime) or regional (water depth, circulation, seasonal) considerations. The reciprocal approach [Liu *et al.*, 2009], which yields similar SST estimates as the logarithmic approach [Kim *et al.*, 2010], is associated with a maximum temperature of 35°C and is therefore also unsuitable for low-latitude greenhouse environments.

TEX₈₆^L- and TEX₈₆^H-based temperature offsets ($\Delta H-L$), both today and in the Paleogene, are similar in deep (>1000 m) water settings but up to 10°C different in shallow (<1000 m) settings, suggesting that the choice of proxy is crucial in the latter setting [Taylor *et al.*, 2013]. $\Delta H-L$ offsets are a function of the GDGT-2/GDGT-3 ([2]/[3]) ratio, such that high $\Delta H-L$ offsets correspond to low [2]/[3] ratios and vice versa. Sedimentary [2]/[3] ratios appear to be elevated when there is a greater contribution of subsurface GDGTs to the sedimentary GDGT pool [Taylor *et al.*, 2013; Kim *et al.*, 2015]. After discarding TEX₈₆ values with potentially problematic GDGT distributions (as discussed above and shown in the supporting information), we use [2]/[3] ratios and $\Delta H-L$ offsets [Taylor *et al.*, 2013] to evaluate the various TEX₈₆ calibrations for each site.

In the SW Pacific (ODP Site 1172, IODP Site 1356, Mid-Waipara River, and Hampden Beach; Figure 1), high $\Delta H-L$ offsets and low [2]/[3] ratios are consistent with sediments deposited in a relatively shallow water setting. It has been shown that the lower TEX₈₆^L-derived SSTs are similar to inorganic and modeled SST estimates [Hollis *et al.*, 2012; Bijl *et al.*, 2013]. TEX₈₆^L-derived SSTs exhibit a stronger latitudinal temperature gradient (~10°C) than TEX₈₆^H, which yields much warmer SW Pacific SSTs (~27–33°C) and a low-latitudinal SST gradient. pTEX₈₆, which has been calibrated to inorganic proxies, gives SW Pacific temperatures similar to those of TEX₈₆^L. All three calibrations exhibit a similar timing and magnitude of cooling through the Eocene [Bijl *et al.*, 2009; Hollis *et al.*, 2012; Bijl *et al.*, 2013]. In the South Atlantic (Seymour Island; Figure 1), [2]/[3] ratios and $\Delta H-L$ offsets are also consistent with sediments deposited in a relatively shallow water setting. There, SSTs derived from inorganic proxies, in this case clumped isotope paleothermometry, are similar to TEX₈₆^L-derived SSTs but colder than TEX₈₆^H [Douglas *et al.*, 2014].

In the North Atlantic (ODP Site 913; Figure 1), TEX₈₆^H and TEX₈₆^L yield similar SSTs, consistent with sediments deposited in a deeper water setting [Myhre *et al.*, 1995; Eldrett *et al.*, 2004]. In contrast, SST estimates derived from pTEX₈₆ are significantly colder. In the western tropical Atlantic (ODP Site 925, ODP Site 929; Figure 1), in a relatively open ocean setting, [2]/[3] ratios are high and $\Delta H-L$ offsets are low, consistent with sediments deposited in a deep-water setting (>1000 m). TEX₈₆^H and TEX₈₆^L all indicate late Eocene cooling, but the magnitude of cooling in TEX₈₆^L is much larger than expected (~7°C). Moreover, pTEX₈₆ and TEX₈₆^L SSTs are colder than expected for a tropical location (21–28°C).

In the Indian Ocean (Tanzania; Figure 1), [2]/[3] ratios are low and $\Delta H-L$ offsets are high; however, there is wide scatter in Tanzania TEX₈₆^L values when compared with inorganic SST estimates, and the overall correlation to SST derived from foraminiferal $\delta^{18}O$ values is stronger when TEX₈₆^H is employed [Hollis *et al.*, 2012]. Overall, the distributions of GDGTs in Eocene sediments agree with previous findings that shallow water settings are associated with large $\Delta H-L$ offsets and small [2]/[3] ratios, and vice versa. However, there are exceptions, including Lomonosov Ridge (ACEX) and ODP Site 511 (Figure 1), which are both shallow water settings with relatively small $\Delta H-L$ offsets. This reinforces previous arguments that water depth is not the primary control on differences between TEX₈₆^H and TEX₈₆^L-derived SSTs [Taylor *et al.*, 2013; Kim *et al.*, 2015]. Instead, we argue that differences are controlled by the magnitude of the subsurface GDGT contribution to sediments, which can be related to water depth but is also governed by the range of factors related to export productivity [Hernández-Sánchez *et al.*, 2014].

Our data also challenge the simple framework that $\text{TEX}_{86}^{\text{L}}$ is most applicable in shallow water settings. In the Atlantic (South Dover Bridge; Figure 1) and Gulf Coastal Plain [Keating-Bitonti *et al.*, 2011], [2]/[3] ratios and $\Delta\text{H-L}$ offsets are consistent with samples deposited in a shallow setting. However, $\text{TEX}_{86}^{\text{L}}$ SST estimates are unexpectedly low for a subtropical setting (22°C) and are, in fact, 2–3°C colder than contemporary SST estimates [Levitus and Boyer, 1994]. A similar problem has been observed in the Gulf of Mexico Coastal Plain during the late Paleocene (~15°C) and PETM (~25°C) [Sluijs *et al.*, 2013]. At Hampden Beach, [2]/[3] ratios and $\Delta\text{H-L}$ offsets are consistent with samples deposited in a shallow setting. However, there are large variations in $\text{TEX}_{86}^{\text{L}}$ SST estimates which are inconsistent with inorganic and organic SST estimates from nearby sites [Bijl *et al.*, 2009; Hollis *et al.*, 2009; Creech *et al.*, 2010; Hollis *et al.*, 2012; Bijl *et al.*, 2013]. These estimates may reflect local variations in SST; alternatively, they may be related to the $\text{TEX}_{86}^{\text{L}}$ index which is far more sensitive to contributions from other archaea and, in particular, the fractional abundance of GDGT-3.

Thus, although $\text{TEX}_{86}^{\text{L}}$ does agree with inorganic proxies in some shallow water settings [Hollis *et al.*, 2009; Hollis *et al.*, 2012; Douglas *et al.*, 2014], there are exceptions. Modern water column investigations suggest that the $\text{TEX}_{86}^{\text{L}}$ calibration should be used with great caution. Recently, Taylor *et al.* [2013] showed that the increase in [2]/[3] ratios with depth is a globally widespread feature of GDGT distributions in the water column, possibly due to the predominance of different Thaumarchaeota communities in the surface mixed layer and subsurface [Villanueva *et al.*, 2014]. The implication is that subsurface export has a markedly stronger impact on $\text{TEX}_{86}^{\text{L}}$ values than on $\text{TEX}_{86}^{\text{H}}$ and, by extension, that the depth-related difference between $\text{TEX}_{86}^{\text{L}}$ - and $\text{TEX}_{86}^{\text{H}}$ -derived SSTs is due to complexities associated with the former. As a result, the following section is restricted to the discussion of $\text{TEX}_{86}^{\text{H}}$ -derived SSTs.

6.2. Sea Surface Temperature Change During the Eocene

Present-day SST rarely exceeds 28–29°C (except in some isolated basins), which some have suggested indicates a homeostatic limit to tropical SST [Ramanathan and Collins, 1991; Kleypas *et al.*, 2008]. This has however been shown to be ill-founded [Pierrehumbert, 1995; van Hooidek and Huber, 2009; Williams *et al.*, 2009] and is not supported by SST records in the more recent geological past [O'Brien *et al.*, 2014]. During the early and middle Eocene, SST estimates from Tanzania [Pearson *et al.*, 2007], Ceara Rise (ODP Site 925; ODP Site 929) [Liu *et al.*, 2009] and the Atlantic Coastal Plain (South Dover Bridge) regularly exceed this modern limit, with $\text{TEX}_{86}^{\text{H}}$ -derived SSTs > 32°C (Figure 7). $\text{TEX}_{86}^{\text{H}}$ SSTs, which are clearly higher than those of today, do not support the existence of a tropical “thermostat” [O'Brien *et al.*, 2014; Pagani, 2014], at least insofar as it is most strictly defined [Ramanathan and Collins, 1991].

Previous work stipulated that if SSTs were truly ~35°C in Tanzania [Pearson *et al.*, 2007], then some tropical regions (e.g., the Western Pacific Warm Pool (WPWP) must have been much hotter [Huber, 2008]. Indeed, our modeling simulations indicate that the WPWP (~34°C) was ~3–4°C warmer than Tanzania (~30–31°C) (Figure 10). Moderately higher tropical temperatures relative to today (>2°C) will significantly increase evaporation rates, latent heat transport [Huber and Sloan, 2000], and the frequency and/or the strength of tropical cyclones [Sriver and Huber, 2007]. Tropical cyclones help to induce ocean mixing which enhances meridional overturning and ocean heat transport. This can reduce the latitudinal temperature gradient by up to 6°C and warm high-latitude oceans by as much as 10°C [Sriver and Huber, 2007; Thomas *et al.*, 2014].

Our record also suggests tropical cooling during the Eocene, albeit of much lesser magnitude than that observed at high southern latitudes [see later; Bijl *et al.*, 2009; Hollis *et al.*, 2009; Creech *et al.*, 2010; Hollis *et al.*, 2012; Bijl *et al.*, 2013]. $\text{TEX}_{86}^{\text{H}}$ indicates ≤2°C of tropical cooling within the Indian Ocean during the middle and late Eocene (45–34 Ma; Figure 8), 3–4°C of cooling within the western equatorial Atlantic during the middle and late Eocene (40–34 Ma; Figure 8), and 4–5°C of cooling within the subtropical Atlantic Coastal Plain between the early and middle Eocene (53–41 Ma; Figure 8). Crucially, middle and late Eocene (47.8–34.0 Ma) tropical cooling is apparent regardless of the calibration. By fitting a nonparametric LOESS regression to our compiled data set, we are able to determine that there was ~2.5°C of long-term tropical surface water cooling between the early and late Eocene (Figure 9b). Jackknifing (the sequential removal of one record at a time) revealed that no single time series overly influences the magnitude of Eocene cooling determined by LOESS regression; however, removal of the South Dover Bridge record does change the pattern of the low-latitude long-term cooling (Figure S7). Slight tropical cooling, as indicated by $\text{TEX}_{86}^{\text{H}}$, remains consistent with inorganic $\delta^{18}\text{O}$ evidence from Tanzania which

Figure 7. Absolute $\text{TEX}_{86}^{\text{H}}$ SST record during the Eocene (55–34 Ma). (a) Low-latitude $\text{TEX}_{86}^{\text{H}}$ SSTs, (b) high-latitude $\text{TEX}_{86}^{\text{H}}$ SSTs, and (c) global benthic foraminiferal $\delta^{18}\text{O}$ stack (updated to GTS2012) in grey with red being the 30 point moving average [Cramer et al., 2011]. Error bars on $\text{TEX}_{86}^{\text{H}}$ are 2.5°C . Filled squares, diamonds, and circles reflect SST estimates from the Atlantic, Indian Ocean, and the SW Pacific, respectively.

suggests slightly cooler temperatures, perhaps coupled with increasing ice volume, in the late Eocene and early Oligocene [Pearson et al., 2007].

For comparison, a nonparametric LOESS regression was fitted through the compiled high-latitude data set. This approach indicates $\sim 6^{\circ}\text{C}$ of high-latitude cooling between the early and late Eocene (Figure 9c). As with the low-latitude compilation, jackknifing revealed that no single record influences the overall magnitude of long-term high-latitude cooling determined by LOESS regression (Figure S8). However, because the IODP 1356 time series has a very high sampling density around the EECO, its removal causes the general cross validation optimization routine to choose a relatively low degree of smoothing, such that the long-term mean high-latitude SST determined without this record exhibits more structure in the Mid and Late Eocene (Figure S8). Nonetheless, long-term average high-latitude cooling, as indicated by $\text{TEX}_{86}^{\text{H}}$ (and also BAYSPAR), is also in agreement with inorganic Mg/Ca SST estimates [Creech et al., 2010; Hollis et al., 2012] and $\delta^{18}\text{O}$ BWT estimates [Cramer et al., 2011] which indicate amplified polar cooling during the Eocene epoch.

6.3. Latitudinal SST Gradients During the Eocene

Our revised SST compilation provides new insights into global cooling during the descent toward the icehouse. During the early Eocene (56.0–47.8 Ma), the temperature difference (ΔT) between the tropics ($2.5\text{--}4.5^{\circ}\text{N}$) and the SW Pacific ($\sim 55\text{--}65^{\circ}$) is very low (ΔT : $< 2^{\circ}\text{C}$) (Figure 7) when compared with modern conditions, as has been extensively noted and discussed elsewhere [Bijl et al., 2009; Hollis et al., 2009; Hollis et al., 2012]. Gradual cooling in the SW Pacific during the middle Eocene (47.8–38.0 Ma) progressively strengthens the southern hemisphere SST gradient (Figure 7). During the late Eocene (38.0–33.9 Ma), the latitudinal SST gradient between the SW Pacific (ODP Site 1772) and the tropics is markedly stronger than the early Eocene (ΔT : $\sim 9^{\circ}\text{C}$) (Figure 7) but remains much smaller than observed today (ΔT : $> 25^{\circ}\text{C}$) [Douglas et al., 2014].

During the late middle Eocene (41.3–38.0 Ma), the temperature difference between the equatorial Atlantic ($2.5\text{--}4.5^{\circ}\text{N}$) and the South Atlantic ($52\text{--}67^{\circ}\text{S}$) is relatively large (ΔT : 14°C) (Figure 7). Although there is cooling in the South Atlantic during the middle late and late Eocene, the latitudinal temperature gradient

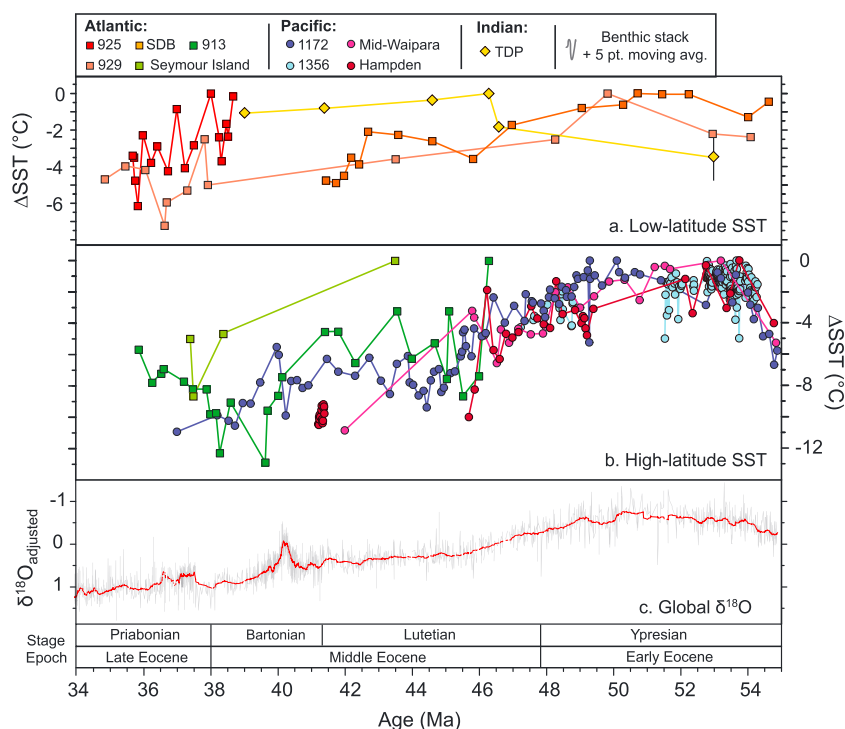

Figure 8. Normalized $\text{TEX}_{86}^{\text{H}}$ SST record during the Eocene (55–34 Ma). (a) Low-latitude $\text{TEX}_{86}^{\text{H}}$ SSTs, (b) high-latitude $\text{TEX}_{86}^{\text{H}}$ SSTs, and (c) global benthic foraminiferal $\delta^{18}\text{O}$ stack (updated to GTS2012) in grey with red being the 30 point moving average [Cramer *et al.*, 2011]. Error bars on $\text{TEX}_{86}^{\text{H}}$ are 2.5°C . Filled squares, diamonds, and circles reflect SST estimates from the Atlantic, Indian Ocean, and the SW Pacific, respectively.

between the equatorial and South Atlantic weakens during this interval (ΔT : 12°C) as a result of tropical cooling (Figures 7 and 8).

During the early middle Eocene (47.8–41.3 Ma), the temperature difference between the equatorial Atlantic (2.5 – 4.5°N) and the North Atlantic (67°N) is also low (ΔT : 5°C) (Figure 7) and similar to the temperature difference between the SW Pacific and the tropics (ΔT : 5°C). Analogous to the SW Pacific, there is no strong cooling trend in the North Atlantic during the early middle Eocene (Figure 7). Immediately following the MECO (~ 40 Ma), the latitudinal SST gradient strengthens (ΔT : $\sim 14^{\circ}\text{C}$) (Figure 7) before weakening during the late middle and late Eocene (38.0–33.9 Ma) (ΔT : $\sim 5^{\circ}\text{C}$).

Previous studies have shown that latitudinal temperature gradients of less than 20°C are difficult for climate models to simulate and require large changes in latitudinal heat transport and/or substantial positive feedbacks acting at high latitudes [Huber and Sloan, 1999; Bice *et al.*, 2000; Huber *et al.*, 2003; Lunt *et al.*, 2012]. As a result, the application of $\text{TEX}_{86}^{\text{H}}$ in high-latitude sites cannot be reconciled with modeled SSTs during the early Eocene [Hollis *et al.*, 2012; Sijp *et al.*, 2014]. However, a closer agreement between proxies and models can be obtained via changes in the physical parameters of the model (e.g., cloud cover) [Sagoo *et al.*, 2013].

6.4. Assessing the Driving Mechanisms: CO_2 , Gateways, or Both?

The apparent tropical SST stability observed by Pearson *et al.* [2007] suggests that mechanisms such as gateway reorganization [Sijp *et al.*, 2011] may have been important in regulating high-latitude cooling during the Eocene [Bijl *et al.*, 2009, 2013]. However, we note that Pearson *et al.* [2007] never argued that tropical SSTs were constant during the Eocene, only that SST change was much smaller than inferred from the oxygen isotopic composition of diagenetically altered foraminifera [Bralower *et al.*, 1995; Dutton *et al.*, 2005]. In fact, a small cooling trend (perhaps coupled with minor ice growth) is apparent in the well-preserved foraminifera in Tanzanian sediments during the middle Eocene (47.8–38.0 Ma) [Pearson *et al.*, 2007]. Although this is not reflected in the original low-resolution Tanzanian TEX_{86} data, our new higher-resolution TEX_{86} data (Figures 7 and 8) and compiled tropical SST record fitted with a nonparametric LOESS regression (Figure 9) indicate the tropics cooled during the middle and late Eocene (47.8–34.0 Ma).

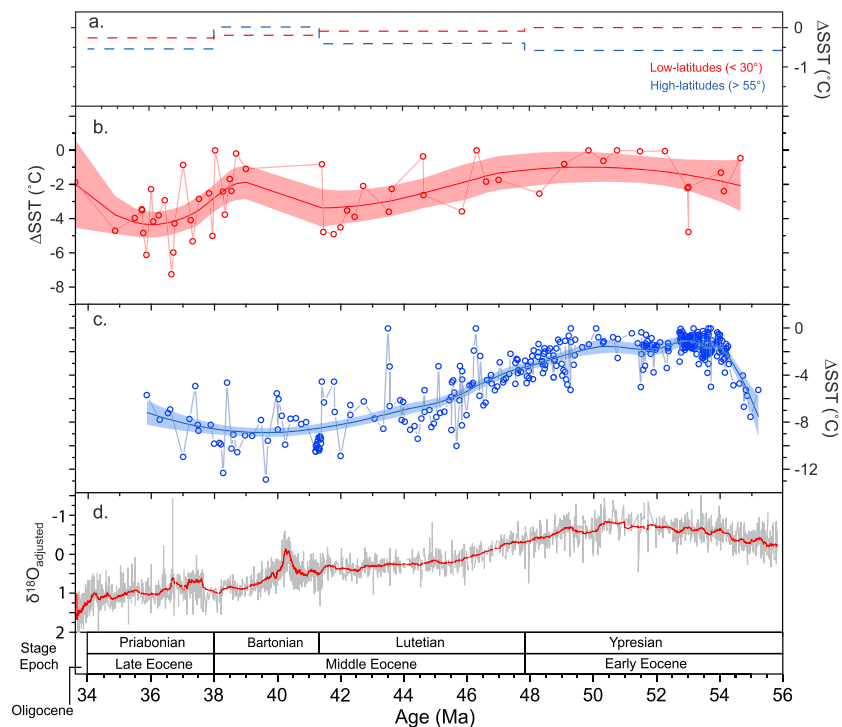

Figure 9. Temperature change during the Eocene (55–34 Ma). (a) HadCM3L model output of SST for low (<30°) and high latitudes (>55°) during each stage of the Eocene. Atmospheric CO₂ is prescribed at 1120 ppmv (4× preindustrial level). (b) Normalized, low-latitude (red) TEX₈₆^H SSTS fitted with a nonparametric LOESS regression. Band reflects the area within which 68% of the data lie. (c) Normalized, high-latitude (blue) TEX₈₆^H SSTS fitted with a nonparametric LOESS regression. Band reflects the area within which 68% of the data lie. (d) Global benthic foraminiferal δ¹⁸O stack in grey (updated to GTS2012) with red being the 30 point moving average [Cramer *et al.*, 2011].

To examine the influence of gateway reorganization upon tropical cooling, we have generated corresponding model-derived SST estimates during each geological Stage of the Eocene using the HadCM3L model (section 2.6; Figures 10, S5 and S6; Tables S2 and S3). The model simulations all have a fixed atmospheric CO₂ concentration of 4× preindustrial values (i.e., 1120 ppmv), and the difference in solar constant between the simulation is relatively small. As such, any temperature variation between the simulations should record the role of ocean gateway reorganization and palaeogeographic change upon global ocean circulation. In our model simulations, the Tasman Gateway is closed during the Ypresian (47.8–56 Ma) with early opening during the Lutetian (41.3–47.8 Ma) and significant deepening during the Priabonian (33.9–38.0 Ma), in agreement with proxy evidence [Stickley *et al.*, 2004; Bijl *et al.*, 2013] (Figure 10). The Drake Passage (DP) is open throughout the Ypresian and Lutetian (Figure 10), in contrast with tectonic and geochemical evidence which suggests that the DP remained closed until the early Bartonian (~41 Ma) [Scher and Martin, 2006; Livermore *et al.*, 2007; Borrelli *et al.*, 2014]. Despite this the total rate of transport (1.3–3 Sverdrups (Sv); Table S1) across the DP during the Ypresian and the Lutetian simulations is very small when compared to modern observations (~130 Sv) [Chidichimo *et al.*, 2014]. The Tethys Ocean remains open between the Ypresian (47.8–56.0 Ma) and the Priabonian (33.9–38.0 Ma) (Figure 10), in line with tectonic evidence [McQuarrie *et al.*, 2003; Allen and Armstrong, 2008].

Our constant-*p*CO₂ model simulations indicate that on a regional scale, low-latitude (<30°) SSTs decrease by ~0.3°C between the early and late Eocene (Figure 9a). During the same interval, compiled, proxy-derived SSTs decrease by 2.5°C (Figure 9b). Based upon this, and assuming the model and boundary conditions are not fundamentally flawed, changes in gateways and palaeogeography can only account for ~10% of the low-latitude, proxy-derived cooling between the early and late Eocene. Although the magnitude of model-derived SST change varies on a site-by-site basis (see Tables S2 and S3), our results indicate that oceanographic change related to palaeogeographic change cannot account for the majority of tropical cooling.

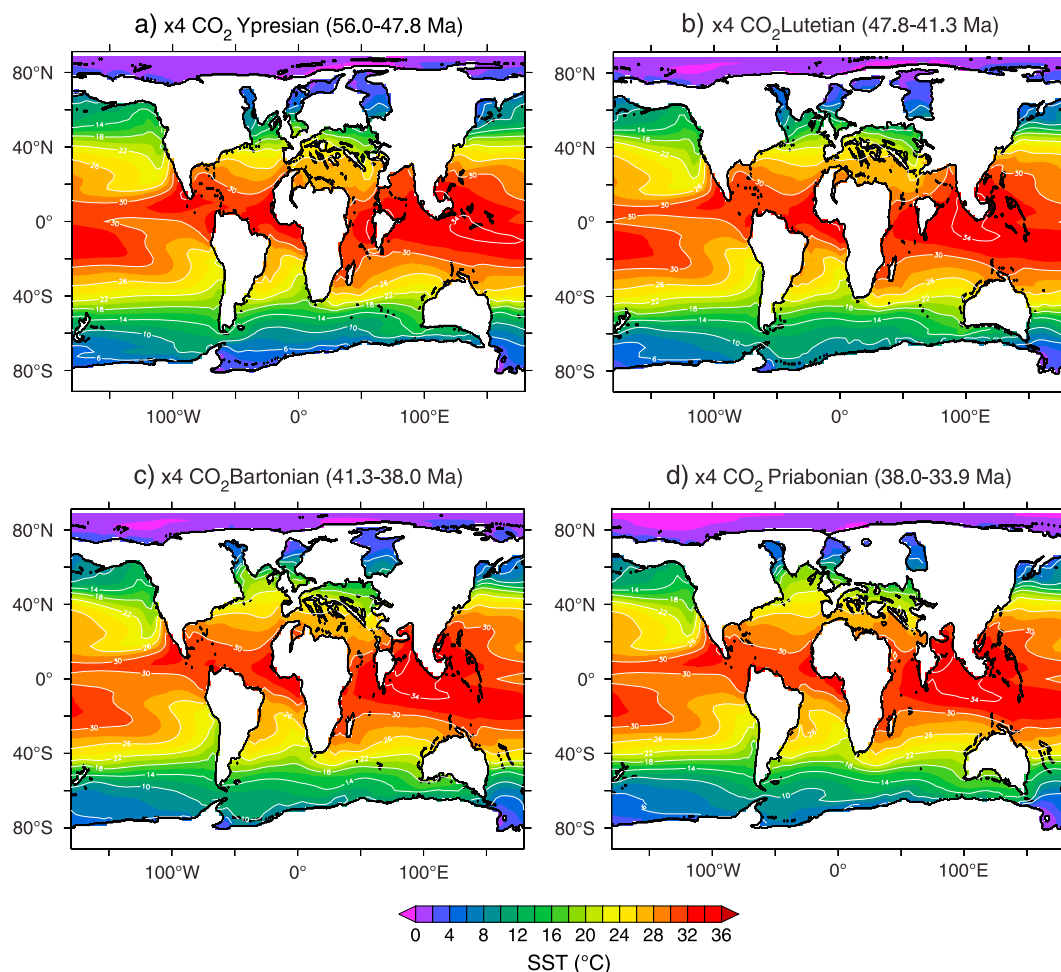

Figure 10. Model-derived SST estimates from four time slice simulations representing the Ypresian (56.0–47.8 Ma), Lutetian (47.8–41.3 Ma), Bartonian (41.3–38.0 Ma), and Priabonian (38.0–33.9 Ma) geological stages. Atmospheric CO₂ is prescribed at 1120 ppmv (4× preindustrial level).

Bathymetric change (such as gateway openings) may have been responsible for other specific regional features. For example, *Sijp et al.* [2009] argue that opening the DP can account for ~5°C of Antarctic cooling under modern-day bathymetries. However, later studies, using inferred Eocene bathymetry, indicate that the magnitude of Antarctic cooling associated with DP opening is negligible (<0.5°C) [*Zhang et al.*, 2010; *Z. Zhang et al.*, 2011; *Lefebvre et al.*, 2012; *Goldner et al.*, 2014]. *Bijl et al.* [2013] argue that initial deepening of the Tasman Gateway ~49–50 Ma coincided with westward throughflow of the proto-Antarctic Circumpolar Current (ACC), resulting in surface water and continental cooling in the SW Pacific and along the East Antarctic margin [*Pross et al.*, 2012; *Bijl et al.*, 2013]. Evidence from neodymium isotopes [*Scher and Martin*, 2006], clumped isotope, and TEX₈₆ paleothermometry [*Bijl et al.*, 2009; *Douglas et al.*, 2014] and model simulations of intermediate complexity [*Sijp et al.*, 2014] also indicate that initial opening of the Tasman Gateway is linked to the intensification of deep-water formation in the Ross Sea [*Bijl et al.*, 2014]. Our model simulations indicate that on a regional scale, high-latitude (>55°) SSTs increase by ~0.4°C between the early and late Eocene (Figure 9a). During the same interval, compiled, high-latitude proxy-derived SSTs decrease by ~6°C (Figure 9b). Based upon this, changes in paleogeography cannot account for the observed high-latitude, proxy-derived cooling during the Eocene (Tables S2–S4). On a local scale, high-latitude, HadCM3L-derived SSTs remain relatively stable (e.g., at the site of ACEX, 913) or increase during the Eocene (e.g., at the site of 1172, Hampden, 1356) (Table S3), indicating that changes in paleogeography are unable to explain the entirety of high-latitude cooling and that other mechanisms, such as CO₂ drawdown, must be invoked. However, it should be noted that models often struggle to

replicate specific oceanographic features. For example, the subtropical East Antarctic Current (EAC) may have extended as far south as $\sim 54^\circ$ during the early Eocene and could have been responsible for warming the surface waters of ODP Site 1172 and New Zealand [Hollis *et al.*, 2012]. In contrast, many models struggle to replicate this phenomena [e.g., Lunt *et al.*, 2012, and references therein]. HadCM3L also exhibits a relatively strong early Eocene latitudinal SST gradient compared to other models (e.g., ECHAM5 or CCSM3) [Lunt *et al.*, 2012], in contradiction to several lines of evidence from proxies [e.g., Bijl *et al.*, 2009].

The evolution of $p\text{CO}_2$ during the Eocene remains poorly constrained, particularly during the early Eocene [Beerling *et al.*, 2011; Hyland and Sheldon, 2013]. Using TEX_{86} and an ensemble of climate model simulations which span the Eocene, we conclude that the some portion of tropical cooling ($\sim 10\%$) can be explained by changes in paleogeography and/or ocean gateways. However, the majority of high-latitude cooling cannot be explained by changes in ocean gateways and, in the absence of other plausible forcing mechanisms, indicates that CO_2 was primarily responsible for global surface water cooling during the Eocene.

7. Descent Into the Icehouse

Long-term gradual cooling during the Eocene culminated in the establishment of permanent ice sheets on the Antarctic continent in the earliest Oligocene. This relatively rapid ice sheet expansion may have been driven by southern ocean gateway opening [Katz *et al.*, 2008, 2011], declining $p\text{CO}_2$ concentrations [DeConto and Pollard, 2003; Pearson *et al.*, 2009; Pagani *et al.*, 2011], or a combination of the two. During this interval, tropical TEX_{86} SST estimates decrease by up to 13°C [Liu *et al.*, 2009]. However, these values are hard to reconcile with Mg/Ca SST estimates [Lear *et al.*, 2008] and U_{37}^K SST estimates [Liu *et al.*, 2009]. This suggests that parameters other than SST are controlling TEX_{86} values during the EOT. Based upon our earlier discussion, we reinvestigate this possibility using the TEX_{86}^H proxy.

From the latest Eocene ($\sim 34\text{--}37$ Ma) into the earliest Oligocene ($\sim 33\text{--}34$ Ma), low-latitude TEX_{86}^H SST estimates decrease, on average, between 0.2 and 5.6°C . However, this does not take into account the full range of cooling which can exceed 10°C within tropical ODP Sites 998 and 803. Both sites are characterized by very high $[2]/[3]$ ratios and low-to-negative $\Delta\text{H-L}$ offsets, suggesting the presence of “deep-water” Thaumarchaeota throughout the late Eocene and early Oligocene [Taylor *et al.*, 2013; Kim *et al.*, 2015]. As deep-water GDGTs can be incorporated into the sedimentary GDGT pool [e.g., Kim *et al.*, 2015], this could account for some of the observed temperature change in tropical settings across the EOT. The intensification of Antarctic bottom water formation and enhanced equatorward transport of Antarctic intermediate water associated with Antarctic glaciation [Katz *et al.*, 2011; Goldner *et al.*, 2014] could have also influenced the depth of GDGT production during this interval. It certainly could have impacted the depth of and temperature change across the tropical thermocline, both of which could have impacted subsurface GDGT production, export, and recorded temperature. Other tropical settings, such as ODP 925 and ODP 929, are characterized by relatively modest cooling ($\sim 3^\circ\text{C}$) and do not appear to be affected by changes in deep-water export of GDGTs. Future studies should attempt to exploit depositional settings which are less likely to be affected by deep-water GDGT export.

8. Conclusions

Using new and previously published GDGT distributions, we have generated a composite TEX_{86} SST record for the Eocene ($55\text{--}34$ Ma). To investigate the influence of archaea other than marine Thaumarchaeota upon Eocene (and Oligocene) TEX_{86} values, we compiled and compared BIT indices, MIs, and %GDGT-0 values from modern and ancient sediments. Our results indicate that Eocene and Oligocene sediments have similar average values as the modern core-top data set but larger standard deviations. Nonetheless, it appears that the effect of archaea other than marine Thaumarchaeota upon Eocene and Oligocene TEX_{86} values is minimal. Our compiled TEX_{86} compilation indicates that between the early and late Eocene, high-latitudes SSTs cooled by $\sim 6^\circ\text{C}$ and low-latitudes SST cooled by $\sim 2.5^\circ\text{C}$. Global sea surface cooling during the Eocene is not in agreement with by fixed- CO_2 HadCM3L model simulations. Therefore, our study provides indirect evidence that drawdown of CO_2 (or some, as of yet unidentified, other factor(s)) was the primary forcing for long-term climatic cooling during the Eocene. Our data set, combined with forthcoming model simulations under a range of different CO_2 levels, paves the way to reconstructing atmospheric CO_2 evolution through the Eocene.

Acknowledgments

Data can be accessed via the online supporting information, via <http://www.pangaea.de/>, or from the author (email: gordon.inglis@bristol.ac.uk). We thank the NERC Life Sciences Mass Spectrometry Facility (Bristol) for analytical support. G.I. thanks Peter Bijl, Peter Douglas, Caitlin Keating-Bitonti, and Appy Sluijs for the raw GDGT distributions. We thank Ian Harding and James Eldrett for helpful discussions on ODP Site 913 and Lucy Edwards and Jean Self-Trail for help with the logistics and sampling of the South Dover Bridge core. G.I. thanks Matt Carmichael, David Naafs, and Marcus Badger for useful discussions. G.I. thanks the UK NERC for supporting his PhD studentship. R.D.P. acknowledges the Royal Society Wolfson Research Merit Award. P.E.J. thanks the Palaeontological Association for a Sylvester-Bradley award. C.H. acknowledges the support of the GNS Science Global Change through Time Programme. G.I., A.F., D.L., G.F., P.P., and R.D.P. were all supported by the NERC Descent into the Icehouse grant (NE/I005714/1). D.L. and A.F. also thank the NERC CPE grant for funding (NE/K014757/1). Finally, we thank the three anonymous reviewers whose comments significantly improved the manuscript.
